A Practice Guideline on Wilson Disease

Eve A. Roberts and Michael L. Schilsky

Preamble

This guideline is intended for use by physicians. It describes preferable up-to-date approaches to the diagnosis and treatment of patients with Wilson disease. As their purpose is to direct patient care, these guidelines should not be considered inflexible mandates. They have been developed in a manner consistent with the American Association for the Study of Liver Diseases Policy Statement on Development and Use of Practice Guidelines.

These guidelines provide data-supported approaches to the diagnosis and management of patients with Wilson disease. They are based on, first, broad-based review of the published literature in pediatrics and medicine including Medline searches on hepatolenticular degeneration and related subjects; and second, 40 accumulated years of personal experience of the authors. In order to standardize recommendations as much as possible, each has been characterized with Roman numerals I through IV to indicate the quality of evidence on which the recommendation is based (Table 1). A significant problem with the literature on Wilson disease is that patients are sufficiently rare to preclude large cohort studies or randomized controlled trials; moreover, most treatment modalities were developed at a time when conventions for drug assessment were less stringent than currently.

Introduction

Wilson disease (WD; hepatolenticular degeneration) was first described in 1912 by Kinnear Wilson as “progressive lenticular degeneration,” a familial, lethal neurologic disease accompanied by chronic liver disease leading to cirrhosis. The association of corneal copper deposits with this disorder was later made by Kayser and Fleischer. Over the next several decades the role of copper in the pathogenesis of WD was established, and the pattern of inheritance was determined to be autosomal recessive. In 1993 the gene that is abnormal in WD was identified. The gene, ATP7B, sometimes also referred to as “WND,” encodes a metal-transporting P-type ATPase, which is expressed mainly in hepatocytes and functions in the transmembrane transport of copper. Absent or reduced function of ATP7B protein leads to decreased hepatocellular excretion of copper into bile. This results in hepatic copper accumulation and injury. Eventually copper is released into the bloodstream and deposited in various other organs, notably the brain, kidneys, and cornea. Failure to incorporate copper into ceruloplasmin is an additional consequence of the loss of functional ATP7B protein. The hepatic production and secretion of the ceruloplasmin protein without copper, apoceruloplasmin, results in the decreased blood level of ceruloplasmin found in most patients with WD due to the reduced half-life of the apoprotein.

WD occurs worldwide with an average prevalence of ~30 affected individuals per million population. It can present clinically as liver disease, as a progressive neurologic disorder (hepatic dysfunction being less apparent or occasionally absent), or as psychiatric illness. WD presents with liver disease more often in children and younger adult patients than in older adults. Symptoms at any age are frequently nonspecific.

WD was uniformly fatal until treatments were developed a half-century ago. WD was one of the first liver diseases for which effective pharmacologic treatment was identified. The first chelating agent introduced in 1951 for the treatment of WD was British anti-lewisite (BAL or dimercaptopropanol). The identification and testing of an orally administered chelator, d-penicillamine, by John Walsh in 1956 revolutionized treatment of this disorder. Other treatment modalities have since been identified, including use of zinc salts to block enteral copper absorption and orthotopic liver transplantation, which may be lifesaving and curative for this disorder.

Clinical Features

Over the years diagnostic advances have enabled more systematic screening of individuals suspected to have WD prior to their development of neurologic symptoms. These include recognition of corneal Kayser-Fleischer rings, Kayser-Fleischer corneal rings, and liver fibrosis and cirrhosis. Kayser-Fleischer rings are horseshoe-shaped deposits of copper in Descemet’s membrane of the cornea. Kayser-Fleischer corneal rings are yellow-Brownish deposits in the peripheral cornea. Liver fibrosis and cirrhosis may be present, with distinctive copper deposition in the liver and other tissues. The diagnosis of WD can be established by measurement of serum copper, ceruloplasmin, and liver biopsy. The diagnosis of WD can also be confirmed by genetic testing for mutations in the ATP7B gene.
rings,\textsuperscript{3} identification of reduced concentrations of ceruloplasmin in the circulation of most patients,\textsuperscript{14} and the ability to measure copper concentration in percutaneous liver biopsy specimens. More recently, molecular diagnostic studies have made it feasible to define patterns of haplotypes or polymorphisms of DNA surrounding \textit{ATP7B}, which are useful for identification of first-degree relatives of newly diagnosed patients. In some patients disease-specific mutations on both alleles of chromosome 13 can be determined.

Patients with cirrhosis, neurologic manifestations, and Kayser-Fleischer rings are easily diagnosed as having WD because they resemble the original clinical description. The patient presenting with liver disease, who is at least 5 years old but under 40 years old, with a decreased serum ceruloplasmin and detectable Kayser-Fleischer rings has been generally regarded as having classic WD.\textsuperscript{15} However, about half of the patients presenting with liver disease do not possess two of these criteria and pose a challenge in trying to establish the diagnosis.\textsuperscript{16} Moreover, as with other liver diseases, patients may present when their clinical disease is comparatively mild.

Because, at the current time, no single, widely available test permits \textit{de novo} genetic diagnosis, a combination of clinical findings and biochemical testing is still necessary to establish the diagnosis of WD (see algorithm in Fig. 1). A molecular genetic strategy ("DNA testing") using haplotype analysis or direct mutation analysis may be effective in identifying affected siblings of probands.

\section*{Spectrum of Disease}

The spectrum of liver disease encountered in patients with WD is summarized in Table 2. The type of the liver disease can be highly variable, ranging from asymptomatic with only biochemical abnormalities to fulminant hepatic failure. Children may be entirely asymptomatic, with hepatic enlargement or abnormal serum aminotransferases found only incidentally. Some patients have a brief clinical illness resembling an acute viral hepatitis, and others may present as clinically indistinguishable from autoimmune hepatitis. Some present with only biochemical abnormalities or histologic findings of steatosis on liver biopsy. Many patients present with signs of chronic liver disease and evidence of cirrhosis, either compensated or decompensated. Patients may present with isolated splenomegaly due to clinically inapparent cirrhosis with portal hypertension. WD may also present as fulminant hepatic failure with an associated Coombs-negative hemolytic anemia and acute renal failure. Some patients

![Fig. 1. Algorithm for assessment of suspected Wilson disease. Patients referred for unexplained liver disease typically have liver enlargement or abnormal serum aminotransferases; those with neurologic or psychiatric symptoms consistent with Wilson disease should have an MR scan of the head performed prior to the hepatologic evaluation. *For patients under 18 years, a penicillamine challenge test may be performed prior to liver biopsy. **Persisting significant symptoms include: hemolysis, unexplained splenomegaly, extrahepatic manifestations of WD (see Table 2), and neurologic or psychiatric disorders.]

\caption{Relating to Quality of Evidence on Which Recommendation Is Based}
\begin{tabular}{|l|l|}
\hline
Grade & Definition \\
\hline
I & Evidence from multiple well-designed randomized controlled trials each involving a number of participants to be of sufficient statistical power \\
II & Evidence from at least one large well-designed clinical trial with or without randomization, from cohort or case-control analytic studies, or well-designed meta-analysis \\
III & Evidence based on clinical experience, descriptive studies, or reports of expert committees \\
IV & Not rated \\
\hline
\end{tabular}

\textbf{NOTE.} These standardized guidelines of the Practice Guideline Committee of the American Association for the Study of Liver Diseases have been modified from the categories of the Infectious Diseases Society of America’s Quality Standards.\textsuperscript{1}
\end{table}
have transient episodes of jaundice, due to hemolysis. Low-grade hemolysis may be associated with WD when liver disease is not clinically evident. In one series hemolysis was a presenting feature in 25 of 220 cases (12%); in these patients hemolysis occurred as a single acute episode, recurrently, or was low-grade and chronic. In a series of 283 Japanese cases of WD, only 3 presented with acute hemolysis alone, but one quarter of the patients had transient episodes of jaundice, due to hemolysis. Patients with apparent autoimmune hepatitis presenting in childhood, or in adults with a suspicion of autoimmune hepatitis that does not readily respond to therapy should be assessed carefully for WD because elevated serum immunoglobulins and detectable nonspecific autoantibodies may be found in both conditions.

Neurologic manifestations of WD typically present later than the liver disease, most often in the third decade of life, but they can present in childhood. Earlier subtle findings may appear in pediatric patients, including changes in behavior, deterioration in schoolwork or inability to perform activities requiring good hand-eye coordination. Handwriting may deteriorate, and cramped small handwriting, as in Parkinson disease (micrographia), may develop. Other common findings in those presenting with neurologic disease include tremor, lack of motor coordination, drooling, dysarthria, dystonia, and spasticity. Because of pseudobulbar palsy, transfer dysphagia may also occur, with a risk of aspiration if severe. Migraine headaches and insomnia may be reported; however, it is unclear whether seizures are more common. Along with behavioral changes, other psychiatric manifestations include depression, anxiety, and even frank psychosis. Many of the individuals with neurologic or psychiatric manifestations may have cirrhosis, but frequently they are not symptomatic from their liver disease.

Patients with WD may present with important extrahepatic manifestations apart from neurologic or psychiatric disease: renal abnormalities including aminoaciduria and nephrolithiasis, skeletal abnormalities such as premature osteoporosis and arthritis, cardiomyopathy, pancreatitis, hypoparathyroidism, and infertility or repeated miscarriages.

#### Age

Even when presymptomatic siblings are excluded, the age at which WD may present or be diagnosed is both younger and older than generally appreciated, although the majority present between ages 5 and 35. The youngest patient reported with cirrhosis due to WD was 3 years old, and others have been reported in the preschool age bracket including a 5-year-old child with fulminant hepatic failure. The oldest patients with WD have been 55 to 62 years old at the time of diagnosis. Recently two siblings were diagnosed in their eighth decade, and the diagnosis was confirmed by molecular studies showing ATP7B mutations.

#### Kayser-Fleischer Ring

Kayser-Fleischer rings represent deposition of copper in Déjérme's membrane of the cornea. When they are visible by direct inspection, they appear as a band of golden-brownish pigment near the limbus. A slit-lamp examination by an experienced observer is required to identify Kayser-Fleischer rings in most patients. They are not entirely specific for WD, since they may be found in patients with chronic cholestatic diseases and in children with neonatal cholestasis. Large series of patients with WD show that Kayser-Fleischer rings are present in only 50% to 62% of patients with mainly hepatic disease at the time of diagnosis. In children presenting with liver disease Kayser-Fleischer rings are usually absent. Kayser-Fleischer rings are almost invariably present in patients with a neurologic presentation, but...
even in these patients they may not be found in 5%. Kayser-Fleischer rings are rarely identified in patients with other types of liver disease, typically chronic cholestatic liver diseases such as primary biliary cirrhosis and primary sclerosing cholangitis. These diseases can usually be distinguished from WD on clinical grounds.

Other ophthalmologic changes may be found. Sunflower cataracts, also found by slit-lamp examination, represent deposits of copper in the lens. These typically do not obstruct vision. Both Kayser-Fleisher rings and sunflower cataracts will gradually disappear with effective medical treatment or following liver transplantation, although the rate of disappearance does not correlate with resolution of clinical symptoms. The reappearance of either of these ophthalmologic findings in a medically treated patient in whom these had previously disappeared suggests noncompliance with therapy.

**Recommendations:** (1) WD should be considered in any individual between the ages of 3 and 45 years with liver abnormalities of uncertain cause (III).

(2) In a patient in whom WD is suspected Kayser-Fleisher rings should be sought by slit-lamp examination by a skilled examiner. The absence of Kayser-Fleisher rings does not exclude the diagnosis of WD, even in patients with predominantly neurologic disease (III).

**Diagnostic Testing**

**Biochemical Liver Tests**

Serum aminotransferase activities are generally abnormal in WD except at a very early age. In many individuals, the degree of elevation of aminotransferase activity may be mild and does not reflect the severity of the liver disease.20,51

**Ceruloplasmin**

This 132-kd protein is synthesized mainly in the liver and is an acute phase reactant. The vast majority of the protein is secreted into the circulation from hepatocytes as a copper-carrying protein containing 6 copper atoms per molecule of ceruloplasmin (holoceruloplasmin) and the remainder as the protein lacking copper (apoceruloplasmin). Ceruloplasmin functions as the major carrier for copper in the blood, accounting for 90% of the circulating copper in normal individuals. Ceruloplasmin also possesses activity as a ferroxidase and acts as an oxidase for substrates such as p-phenylamine diamine and o-dianisidine. Levels of serum ceruloplasmin may be measured enzymatically by their copper-dependent oxidase activity towards these substrates, or by antibody-dependent assays such as radioimmunoassay, radial immunodiffusion, or nephelometry. Results generally are regarded as equivalent, but immunologic assays may overestimate ceruloplasmin concentrations since they do not discriminate between apoceruloplasmin and holoceruloplasmin.

There are reports of the development of a monoclonal antibody that selectively discriminates between the two forms of ceruloplasmin, but this has never been successfully developed for use in clinical testing nor validated in populations with liver disease. Serum ceruloplasmin concentrations are elevated by acute inflammation, in states associated with hyperestrogenemia such as pregnancy, estrogen supplementation, and use of the oral contraceptive pill.

Levels of serum ceruloplasmin are physiologically very low in early infancy to the age of 6 months, peak at higher than adult levels in early childhood (at approximately 300-500 mg/L), and then settle to the adult range. Serum ceruloplasmin is typically decreased in patients with WD, but serum ceruloplasmin may be low in certain other conditions with marked renal or enteric protein loss or with severe end-stage liver disease of any etiology. Low levels of ceruloplasmin and/or pancytopenia have been recognized in patients with copper deficiency when trace elements were not added to parenteral alimentation, and in patients with Menkes disease, an X-linked disorder of copper transport due to mutations in ATP7A. Patients with the rare disorder aceruloplasminemia lack the protein entirely due to mutations in the ceruloplasmin gene on chromosome 3, but these patients exhibit hemosiderosis, not copper accumulation.

A serum ceruloplasmin level less than 200 mg/L (<20 mg/dL, although there are different laboratory ranges) has been considered consistent with WD and diagnostic, if associated with Kayser-Fleisher rings. A prospective study of using serum ceruloplasmin alone as a screening test for WD in patients referred with liver disease showed that subnormal ceruloplasmin had a positive predictive value of only 6%: of 2,867 patients tested, only 17 had subnormal ceruloplasmin and only 1 of these was found to have WD.6 Other recent reports indicate the scope of this problem. In one series, 12 of 55 WD patients had normal ceruloplasmin and no Kayser-Fleisher rings. In another study, 6 of 22 WD patients had serum ceruloplasmin greater than 170 mg/L (>17 mg/dL) and of these, 4 had no Kayser-Fleisher rings. In children, 3 of 26 patients had ceruloplasmin greater than 150 mg/L (>15 mg/dL) and in an early study 10 of 28 children with WD had serum ceruloplasmin ≥200 mg/L (≥20 mg/dL). Most reports based on several decades of experience from the mid-1950s onward indicate that 90% to 100% of patients had serum ceruloplasmin in the subnormal range. Using serum ceruloplasmin to identify patients with WD is further complicated by overlap with some
heterozygotes. Approximately 20% of heterozygotes have decreased levels of serum ceruloplasmin.

**Uric Acid**

Serum uric acid may be decreased at presentation with symptomatic hepatic or neurologic disease because of associated renal tubular dysfunction (Fanconi syndrome). Insufficient evidence is available to determine the predictive value of this finding.

**Recommendation:** (3) Serum ceruloplasmin should be routinely measured during the evaluation of unexplained hepatic, neurologic, or psychiatric abnormalities in children and adults through middle age. An extremely low serum ceruloplasmin level (<50 mg/L or <5 mg/dL) should be taken as strong evidence for the diagnosis of WD. Modestly subnormal levels suggest that further evaluation is necessary. Serum ceruloplasmin within the normal range does not exclude the diagnosis (III).

**Serum Copper**

Although a disease of copper overload, the total serum copper (which includes copper incorporated in ceruloplasmin) in WD is usually decreased in proportion to the decreased ceruloplasmin in the circulation. In patients with severe liver injury, serum copper may be within the normal range despite a decreased serum ceruloplasmin level. In the setting of acute fulminant hepatic failure due to WD, levels of serum copper may be markedly elevated due to the sudden release of the metal from tissue stores. Normal or elevated serum copper levels in the face of decreased levels of ceruloplasmin indicate an increase in the concentration of copper not bound to ceruloplasmin in the blood (nonceruloplasmin-bound copper).

The serum nonceruloplasmin-bound copper concentration has been proposed as a diagnostic test for WD. It is elevated above 25 μg/dL in most untreated patients (normal <15 μg/dL). Nonceruloplasmin-bound copper is usually estimated from the serum copper and ceruloplasmin. The amount of copper associated with ceruloplasmin is approximately 3.15 μg of copper per milligram of ceruloplasmin. Thus the nonceruloplasmin copper is the difference between the serum copper concentration in μg/dL and 3 times the serum ceruloplasmin concentration in mg/dL.69-71 (For SI units, both serum copper and ceruloplasmin should be expressed as per liter; the conversion factor is unchanged, but the normal reference value is <150 μg/L.) The serum nonceruloplasmin copper concentration may be elevated in acute liver failure of any etiology, not only WD,67,72 and it may be elevated in chronic cholestasis73 and in cases of copper intoxication from ingestion or poisoning.

The major problem with nonceruloplasmin-bound copper as a diagnostic test for WD is that it is dependent on the adequacy of the methods for measuring both serum copper and ceruloplasmin. Therefore it is often difficult to interpret. It is of more value in patient monitoring of pharmacotherapy than in the diagnosis of WD. Unclear results should be correlated with the 24-hour urinary copper excretion. Nonceruloplasmin-bound copper concentration <5 μg/dL in combination with exceedingly low 24-hour urinary copper excretion may signal systemic copper depletion that can occur in some patients with prolonged treatment.

**Urinary Copper Excretion**

The amount of copper excreted in the urine in a 24-hour period may be helpful for diagnosing WD and for monitoring of treatment. The 24-hour urinary excretion of copper reflects the amount of nonceruloplasmin-bound copper in the circulation. Basal measurements can provide useful diagnostic information so long as copper does not contaminate the collection apparatus and the urine collection is complete. There is too much variability in the copper content in spot urine specimens for them to be utilized. Volume and total creatinine excretion in the 24-hour urine collection are measured to assess completeness. The conventional level taken as diagnostic of WD is greater than 100 μg/24 hours (>1.6 μmoles/24 hours) in symptomatic patients.72 Recent studies indicate that basal 24-hour urinary copper excretion may be less than 100 μg at presentation in 16% to 23% of patients diagnosed with WD.16,46,48 The reference limits for normal 24-hour excretion of copper vary among clinical laboratories. Many laboratories take 40 μg (0.6 μmoles) per 24 hours as the upper limit of normal. This appears to be a better threshold for diagnosis.37,74

Interpreting 24-hour urinary copper excretion can be difficult due to overlap with findings in other types of liver disease, and heterozygotes may also have intermediate levels.72 Patients with certain chronic liver diseases, including autoimmune hepatitis, may have basal 24-hour copper excretion in the 100 to 200 μg/24 hours (1.6-3.2 μmoles/24 hours) range.75 In one study of patients with chronic active liver disease, 5 of 54 patients had urinary copper excretions above 100 μg/24 hours43; overlap has also been found in children with autoimmune hepatitis.55

Urinary copper excretion with D-penicillamine administration may be a useful diagnostic adjunctive test. This test has only been standardized in a pediatric population47 in which 500 mg of D-penicillamine was administered orally at the beginning and again 12 hours later during the 24-hour urine collection irrespective of body weight. Compared with a spectrum of other liver diseases includ-
ing autoimmune hepatitis, primary sclerosing cholangitis, and acute liver failure, a clear differentiation was found when greater than 1,600 μg copper/24 hours (>25 μmoles/24 hours) was excreted. This test has been used in adults, but many of the reported results of this test in adults utilized different dosages and timing for administration of the D-penicillamine.16,72,75

Measurement of the basal 24-hour urinary excretion of copper forms part of the assessment to screen siblings for WD, but it has not been validated as the sole test for screening.

**Recommendations:** (4) The basal 24-hour urinary excretion should be measured as an aid to the diagnosis of WD. Basal 24-hour urinary excretion of copper in WD is typically greater than 100 μg (1.6 μmoles) in symptomatic patients, but a finding greater than 40 μg (>0.6 μmoles or >600 nmoles) may indicate WD and requires further investigation (II).

(5) In children, penicillamine challenge studies may provide evidence for the diagnosis of WD if urinary excretion of greater than 1,600 μg copper/24 hours (>25 μmoles/24 hours) is found following the administration of 500 mg of D-penicillamine at the beginning and again 12 hours later during the 24-hour urine collection. The predictive value of this test in adults is unknown (II).

**Hepatic Parenchymal Copper Concentration**

Hepatic copper content ≥250 μg/g dry weight remains the best biochemical evidence for WD. Normal concentrations rarely exceed 50 μg/g dry weight of liver. The concentration of hepatic copper in heterozygotes, although frequently elevated above normal, does not exceed 250 μg/g dry weight. In long-standing cholestatic disorders, hepatic copper content may also be increased above this level. Markedly elevated levels of hepatic copper may also be found in idiopathic copper toxicosis syndromes such as Indian childhood cirrhosis.47

Biopsies for quantitative copper determination should be taken with a disposable Jamshidi or Tru-Cut needle and placed dry in a copper-free container. A core (or part of a biopsy core) of liver should be dried overnight in a vacuum oven or, preferably, frozen immediately and kept frozen for shipment to a laboratory for quantitative copper determination. Paraffin-embedded specimens can also be analyzed for copper content.

The major problem with hepatic parenchymal copper concentration is that in later stages of WD, distribution of copper within the liver is often inhomogeneous. In extreme cases nodules lacking histochemically detectable copper are found next to the cirrhotic nodule with abundant copper. Thus, the concentration can be underestimated due to sampling error. In a pediatric study, sampling error was sufficiently common to render this test unreliable in patients with cirrhosis and clinically evident WD.47 In general, the accuracy of measurement is improved with adequate specimen size: at least 1 cm of biopsy core length should be submitted for analysis.76

**Radiocopper Study**

In WD patients with a normal serum ceruloplasmin, radiocopper incorporation into this protein is significantly reduced compared with normal individuals and most heterozygotes. The failure to incorporate copper into the plasma protein within the hepatocyte occurs in all homozygotes with the disease. This test is now rarely used because of the difficulty in obtaining isotope. An experimental alternative to using radiocopper is the use of a nonradioactive isotope for copper, 65Cu, which can be detected by mass spectroscopic methods; however, this methodology has difficulty in distinguishing heterozygotes from patients and is not routinely available.

**Recommendation:** (6) Hepatic parenchymal copper content greater than 250 μg/g dry weight provides critical diagnostic information and should be obtained in cases where the diagnosis is not straightforward and in younger patients. In untreated patients, normal hepatic copper content (<40 to 50 μg/g dry weight) excludes a diagnosis of WD (III).

**Liver Biopsy Findings**

The earliest histologic abnormalities in the liver include mild steatosis (both microvesicular and macrovesicular), glycogenated nuclei in hepatocytes, and focal hepatocellular necrosis.78,79 The liver biopsy may show classic histologic features of autoimmune hepatitis (the so-called “chronic active hepatitis” picture). With progressive parenchymal damage, fibrosis and subsequently cirrhosis develop.80 Cirrhosis is frequently found in most patients by the second decade. It is usually macronodular, although occasionally micronodular. There are some older individuals who do not appear to have cirrhosis even after this time, although they have neurologic disease; however, their hepatic histology is not normal.16 In the setting of fulminant hepatic failure, there is marked hepatocellular degeneration and parenchymal collapse, typically on the background of cirrhosis. Apoptosis of...
Detection of copper in hepatocytes by routine histochemical evaluation is highly variable. In early stages of the disease, copper is mainly in the cytoplasm bound to metallothionein, and it is not histochemically detectable; later, copper is found predominantly in lysosomes. The amount of copper varies from nodule to nodule in cirrhotic liver and may vary from cell to cell in precirrhotic stages. The absence of histochemically identifiable copper does not exclude WD, and for screening for WD this test has a poor predictive value. Copper-binding protein can be stained by various methods including the rhodamine or orcein stain. The more sensitive Timms sulphur stain for copper binding protein is not routinely applied.

Ultrastructural analysis of liver specimens at the time of presentation reveals specific mitochondrial abnormalities. Specific patterns of mitochondrial abnormalities may be visible among affected family members. Typical findings include variability in size and shape, increased density of the matrix material, and numerous inclusions including lipid and fine granular material that may be copper. The most striking alteration is increased intracristal space with dilatation of the tips of the cristae, creating a cystic appearance. In the absence of cholestasis, these changes are considered to be essentially pathognomonic of WD. With adequate chelation treatment, these changes may resolve. At later stages of the disease, dense deposits within lysosomes are present. Ultrastructural analysis may be a useful adjunct for diagnosis in helping to distinguish between heterozygous carriers and patients, but if not routine, it requires advanced planning so that part of the specimen is placed in the proper preservative when biopsy is performed.

Development of hepatocellular carcinoma is a rarely reported complication of WD. Screening for hepatocellular carcinoma has not been recommended for WD patients; however, objective data are lacking and the cost effectiveness of screening in this population needs to be examined prospectively for those with cirrhosis at the time of presentation.

Neurologic Findings and Radiologic Imaging of the Brain

Neurologic disease may manifest as motor abnormalities with Parkinsonian characteristics of dystonia, hyperkinesia, and rigidity, choreic or pseudoclonol, with tremors and dysthria. Disabling symptoms include muscle spasms, which can lead to contractures, dysarthria and dysphonia, and dysphagia. At this stage of disease, magnetic resonance imaging (MR) of the brain or computerized tomography may detect structural abnormalities in the basal ganglia. Most frequently found are increased density on computerized tomography and hyperintensity on T2 MR imaging in the region of the basal ganglia. MR may be more sensitive in detecting these lesions. Abnormal findings are not limited to this region, and other abnormalities have been described. Significant abnormalities on brain imaging may even be present in some individuals prior to the onset of symptoms.

Neurologic evaluation should be performed on all patients with WD. Consultation with a neurologist or movement disorder specialist should be sought for evaluation of patients with evident neurologic symptoms before treatment or soon after treatment is initiated. A specific rating scale based on that for Huntington disease was used to evaluate patients with WD in clinical trials; however, this has never been tested outside of this research setting.

Recommendation: (7) Neurologic evaluation and radiologic imaging of the brain, preferably by MR, should be considered prior to treatment in all patients with neurologic WD and should be part of the evaluation of any patient presenting with neurologic symptoms consistent with WD (III).

Genetic Studies

Molecular genetic studies are becoming available for clinical use, but only pedigree analysis using haplotypes based on polymorphisms surrounding the WD gene is commercially available from specific clinical laboratories. This analysis requires the identification of a patient within the family (the proband) by clinical and biochemical studies as above. After the mutation or haplotype, based on the pattern of di- and trinucleotide repeats around ATP7B, is determined in the proband, the same specific regions of the DNA from first-degree relatives can be tested to determine whether or not they are unaffected, heterozygous, or indeed patients. Prenatal testing can also be performed but has limited application clinically since diagnosis early in life allows appropriate timing for treatment.

The utility of direct mutation analysis is currently limited since most patients are compound heterozygotes with a different mutation on each allele, and currently over 200 mutations of ATP7B have been identified (see www.medgen.med.ualberta.ca/database.html for updated catalogue). De novo diagnoses by molecular studies remain difficult at present due to the large numbers of disease-specific mutations of ATP7B, and with current methodology analysis remains labor intensive and tedious. Mutation analysis is a valuable but not readily available diagnostic strategy for certain well-defined populations exhibiting a limited spectrum of ATP7B mutations. Some
populations with a single predominant mutation include Sardinian,102 Icelandic,103 Korean,104 Japanese,105 and in the Canary Islands.74 Certain populations in Eastern Europe also show predominance of the H1069Q mutation.106,107

Genotype to phenotype correlations in WD are hampered by the high prevalence of compound heterozygotes, patients with WD who carry one each of two different mutations in ATP7B. Studies in homozygotes suggest that mutations affecting critical portions of the protein including copper-binding domains or the ATPase loop may lead to early onset of hepatic disease,108 but strict concordance is difficult to prove.99,109

Recommendation: (8) When possible, genetic diagnosis based on haplotype analysis should be used for family screening of first-degree relatives of patients with WD (III).

Diagnostic Considerations in Specific Target Populations

“Mimic” Liver Diseases

Patients with WD, especially younger ones, may have clinical features and histologic findings on liver biopsy indistinguishable from autoimmune hepatitis.19–21 All children with apparent autoimmune hepatitis and any adult patient with the presumptive diagnosis of autoimmune hepatitis failing to respond rapidly and appropriately to corticosteroid treatment must be carefully evaluated for WD. Occasional patients with WD may benefit from a brief course of treatment with corticosteroids along with appropriate specific treatment for WD.21 Hepatic steatosis in WD is rarely as severe as in nonalcoholic steatohepatitis (NASH). Nevertheless occasional patients with WD resemble NASH convincingly or may have both diseases.

Fulminant Liver Failure

Most patients with the fulminant hepatic failure presentation of WD have a characteristic pattern of clinical and biochemical findings110–115:
1. Coombs-negative hemolytic anemia with features of acute intravascular hemolysis
2. Coagulopathy unresponsive to parenteral vitamin K administration
3. Rapid progression to renal failure
4. Relatively modest rises in serum aminotransferases (typically <2,000 IU/L) from the beginning of clinical illness
5. Normal or markedly subnormal serum alkaline phosphatase (typically <40 IU/L)116
6. Female to male ratio of 2:1

A high level of clinical suspicion is essential for the diagnosis; simple indices of laboratory findings do not reliably distinguish patients with fulminant hepatic failure from those with acute liver failure due to viral infection or drug toxicity.117 The relatively modest elevations of serum aminotransferase activity seen in most of these individuals compared with acute liver failure of other etiologies often leads to an underestimate of the severity of the disease. Serum ceruloplasmin is usually decreased; serum copper and 24-hour urinary excretion of copper are greatly elevated. In many facilities these results are not available in a timely manner, and diagnosis has to rest on clinical features. Kayser-Fleischer rings may be identified to support the diagnosis of WD but may be absent in 50% of these patients. Other findings, such as lunulae ceruleae, are rarely detected but should suggest further evaluation to exclude WD. Expeditious diagnosis is critically important since these patients require urgent liver transplantation to survive. In some patients with fulminant hepatic failure, the serum aspartate aminotransferase (AST) level may be higher than the serum alanine aminotransferase (ALT) level, potentially reflecting mitochondrial damage, but this finding is not sufficiently invariant to be diagnostic.45,51,118,119 A more common finding in this setting is the low level of serum alkaline phosphatase activity and a ratio of alkaline phosphatase (IU/L) to total bilirubin (in mg/dL) of less than 2.119 A prognostic index to be applied at the time of diagnosis of acute fulminant WD that may be helpful to predict survival without liver transplantation has been developed based on total serum bilirubin, AST, and prolongation of prothrombin time120; although it defines extreme cases adequately, it does not discriminate between survivors and nonsurvivors in patients with moderately severe disease reliably.

Because this is usually the first presentation of WD in the patient, underlying liver disease is not suspected, although cirrhosis is typically present.45 It is thought that an intercurrent illness such as a viral infection121 or drug toxicity may touch off this rapidly progressive liver disease. Rare patients have acute liver failure from viral hepatitis and are found at that time to have underlying WD.122,123

Recommendations: (9) Patients in the pediatric age bracket who present a clinical picture of autoimmune hepatitis should be investigated for WD. Adult patients with atypical autoimmune hepatitis or who respond poorly to standard corticosteroid therapy should also be investigated for WD (III).

(10) WD should be considered in the differential diagnosis of patients presenting with nonalcoholic fatty liver or who have pathologic findings of NASH (IV).
(11) WD should be suspected in any patient presenting with fulminant hepatic failure with Coombs-negative intravascular hemolysis, modest elevations in serum aminotransferases, low serum alkaline phosphatase, and ratio of alkaline phosphatase to bilirubin of less than 2 (III).

**Family Screening**

First-degree relatives of any patient newly diagnosed with WD must be screened for WD. Assessment should include brief history relating to jaundice, liver disease, and subtle features of neurologic involvement; physical examination; serum copper, ceruloplasmin, and liver function tests including aminotransferases, albumin, conjugated and unconjugated bilirubin; slit-lamp examination of the eyes for Kayser-Fleischer rings; and measurement of basal 24-hour urinary copper. Individuals without Kayser-Fleischer rings who have subnormal ceruloplasmin and abnormal liver function tests should undergo liver biopsy to confirm the diagnosis. If available, haplotype studies should be obtained and may be used as primary screening. Treatment should be initiated for all individuals over 3 to 4 years old identified as patients by family screening.

**Recommendation:** (12) First-degree relatives of any patient newly diagnosed with WD must be screened for WD. Assessment should include history and physical examination, serum aminotransferases and biochemical tests of hepatic synthetic function, complete blood count, and ceruloplasmin. Kayser-Fleischer rings should be sought by slit-lamp examination. The basal 24-hour urinary copper excretion should be measured. Genotype or haplotype studies based on findings in the proband should be performed (II).

**Treatment**

For the first half a century following the description of WD there was no effective treatment for this progressively fatal disorder. Since controlled trials were not possible when treatment became available, treatments for WD historically progressed from the intramuscular administration of BAL to the more easily administered oral penicillamine. Although there are studies showing dose response of penicillamine and the resultant cupriuresis, initial clinical use was limited by the availability of the drug itself and empiric doses were chosen because no formal dose response studies for efficacy over time were carried out. Interestingly, when these treatments initially became available, treatment was first reserved for symptomatic patients because there were no good diagnostic tests available to identify presymptomatic disease. Simultaneous with the advances in diagnostic testing for WD, a new era was ushered in by the recognition that significant morbidity and mortality could be prevented by the treatment of asymptomatic patients. The development of alternative agents to penicillamine was stimulated by the inability of some patients to tolerate this drug. Trientine was developed and introduced specifically for patients who developed adverse reactions to penicillamine. Zinc was developed separately, as was tetrathiomolybdate, which was used by veterinarians for copper poisoning in animals. Today, the mainstay of treatment for WD remains lifelong pharmacologic therapy; liver transplantation, which corrects the underlying hepatic defect in WD, is reserved for severe or resistant cases.

In general, the approach to treatment is dependent on whether there is active disease or symptoms, whether neurologic or hepatic, or whether the patient is identified prior to the onset of clinical symptoms. We believe this distinction helps in determining the choice of therapy and the dosages of medications utilized, although there are no studies in which this approach has been systematically explored. The recommended initial treatment of symptomatic patients or those with active disease is with chelating agents, although there are some reports showing that primary treatment with zinc may be adequate for some individuals. The largest treatment experience worldwide is still with D-penicillamine; however, there is now more frequent consideration of trientine for primary therapy. Data now exist showing the efficacy of trientine when treating patients with decompensated neurologic or hepatic disease. Previous limitations to the use of trientine were its limited supply and concerns about its continued availability; many clinicians lack experience with this medication. Combination therapy, in which zinc is utilized in conjunction with a chelating agent (temporally separated), has a theoretical basis in both blocking copper uptake and eliminating excess copper. There are only preliminary reports of the simultaneous use of chelators and zinc as primary therapy, and future studies are needed to determine whether efficacy is greater than with therapy with a chelator alone. Studies of the use of tetrathiomolybdate as an alternative chelating agent for the initial treatment of neurologic WD are ongoing.

Once disease symptoms or biochemical abnormalities have stabilized, typically 2 to 6 months following initiation of therapy, maintenance dosages of chelators or zinc therapy can be used for treatment. Patients presenting without symptoms may be treated with either maintenance dosages of a chelating agent or with zinc from the outset. Failure to comply with lifelong therapy has led to recurrent symptoms and liver failure, the latter requiring liver transplantation for survival. Monitoring of therapy includes monitoring for compliance as well as for potential treatment-induced side effects.
Available Treatments (Table 3)

**D-Penicillamine.** Penicillamine was introduced as the first oral agent for treating WD in 1956.\(^{13}\) It was identified as a breakdown product of penicillin but is actually the sulfhydryl-bearing amino acid cysteine doubly substituted with methyl groups. Like dimercaptopropanol (British anti-lewisite, or BAL) it has a free sulfhydryl group, which functions as the copper chelating moiety. Penicillamine is currently synthesized as such, and contamination with penicillin is not an issue; likewise, the racemic mixture, which tends to interfere with pyridoxine action, is no longer used.

The major effect of penicillamine in WD is to promote the urinary excretion of copper. Penicillamine may also act by inducing metallothionein in individuals with WD.\(^{125}\) Penicillamine also interferes with collagen cross-linking\(^{126}\) and has some immunosuppressant actions.\(^{127}\) It is a general chelator of metals, is used to treat cystinosis, and has been used as an immunosuppressant in rheumatoid arthritis.

Penicillamine is rapidly absorbed from the gastrointestinal tract with a double-peaked curve for intestinal absorption.\(^{128,130}\) Uptake may occur by an unusual mechanism: disulfide binding to the enterocyte membrane followed by pinocytosis. If taken with a meal, absorption of the drug is decreased overall by about 50%.\(^{130,131}\) Total bioavailability is estimated at 40% to 70%.\(^{129,132}\) Once absorbed, 80% of penicillamine circulates bound to plasma proteins; there is little free penicillamine in the plasma, as it forms inactive dimers or binds to cysteine. Over 80% of penicillamine excretion is via the kidneys. The excretion half-life of penicillamine is on the order of 1.7–7 hours,\(^{128,130,132}\) but there is considerable interindividual variation, and penicillamine or its metabolites can be found in the urine months after the drug has been discontinued.\(^{133}\)

The initial use of penicillamine was for the treatment of symptomatic patients, and numerous studies attest to the effectiveness of penicillamine as treatment for WD.\(^{66,134-139}\) Worsening of neurologic symptoms has been reported in 10% to 50% of those treated with penicillamine during the initial phase of treatment.\(^{140,141}\) For patients with symptomatic liver disease, the time for evidence of recovery of synthetic function and improvement in clinical signs such as jaundice and ascites is typically during the first 2 to 6 months of treatment, but further recovery can occur during the first year of treatment.\(^{33}\) Failure to comply with therapy has led to significant progression of liver disease and liver failure in 1 to 12 months following discontinuation of treatment, resulting in death or necessitating liver transplantation.\(^{142}\)

Penicillamine use is associated with numerous side effects. Severe side effects requiring the drug to be discontinued occur in 20% to 30% of patients. Early sensitivity reactions marked by fever and cutaneous eruptions, lymphadenopathy, neutropenia or thrombocytopenia, and proteinuria may occur during the first 1 to 3 weeks. Penicillamine should be discontinued immediately if early sensitivity occurs; the availability of alternative medications makes a trial of prednisone cotreatment unnecessary. Late reactions include nephrotoxicity, usually heralded by proteinuria or the appearance of other cellular

elements in the urine, for which discontinuation of penicillamine should be immediate. Other late reactions include a lupus-like syndrome marked by hematuria, proteinuria, positive antinuclear antibody, and with higher dosages of penicillamine no longer typically used for treating WD, Goodpasture syndrome. Significant bone marrow toxicity includes severe thrombocytopenia or total aplasia. Dermatologic toxicities reported include progeric changes in the skin and elastosis perforans serpiginosa, pemphigus or pemphigoid lesions, lichen planus, and aphthous stomatitis. Very late side effects include nephrotoxicity, severe allergic response upon re-starting the drug after it has been discontinued, myasthenia gravis, polymyositis, loss of taste, IgA depression, and serous retinitis. Hepatotoxicity has been reported.\(^{143}\) Hepatic siderosis has been reported in association with treated patients with reduced levels of serum ceruloplasmin and nonceruloplasmin-bound copper.\(^{144}\)

Tolerability of penicillamine may be enhanced by starting with incremental doses, 250 to 500 mg/d, increased by 250 mg increments every 4 to 7 days to a maximum of 1,000 to 1,500 mg/d in 2 to 4 divided dosages. Maintenance dose is usually 750 to 1,000 mg/d administered in 2 divided doses. Dosing in the child is 20 mg/kg/d rounded off to the nearest 250 mg and given in 2 or 3 divided doses. Penicillamine is best administered 1 hour prior to or 2 hours after meals as food inhibits its absorption. Closer proximity to meals is acceptable if it ensures compliance. Apart from numerous adverse side effects detailed above, another feature of treatment with D-penicillamine is that the serum ceruloplasmin tends to decrease after initiation of treatment. Serum ceruloplasmin may either remain low or increase over the term of chronic treatment, the latter occurring in some patients with severe hepatic insufficiency as they recover synthetic function in response to treatment.

Adequacy of treatment is monitored by measuring 24-hour urinary copper excretion while on treatment. This should run in the vicinity of 200 to 500 \(\mu\)g (3-8 \(\mu\)moles) per day on treatment. Regular supplementation with pyridoxine is required at a dose of 25 to 50 mg daily. In addition, estimate of nonceruloplasmin-bound copper shows normalization of the nonceruloplasmin-bound copper concentration with effective treatment.

**Trientine.** Trientine (triethylene tetramine dihydrochloride or 2,2,2-tetramine, also known by its official short name trien) is one of a family of chelators with a polyamine-like structure chemically distinct from penicillamine. It lacks sulphydryl groups, and copper is chelated by forming a stable complex with the 4 constituent nitrogens in a planar ring.

Trientine was introduced in 1969 as an alternative to penicillamine. Few data exist about the pharmacokinetics of trientine. It is poorly absorbed from the gastrointestinal tract, and what is absorbed is metabolized and inactivated.\(^{145,146}\) About 1% of the administered trientine and about 8% of the biotransformed trientine metabolite, acetyltrien, ultimately appears in the urine. The acetyltriens is a less effective chelator than trien. The amounts of urinary copper, zinc, and iron increase in parallel with the amount of trientine that appears in the urine.\(^{147}\)

Like penicillamine, trientine promotes copper excretion by the kidneys. Whether trientine is a weaker chelator of copper than penicillamine is controversial,\(^{135,148,149}\) and dose adjustments can compensate for small differences. Trientine and penicillamine may mobilize different pools of body copper.\(^{148}\)

Trientine is an effective treatment for WD\(^{142,150}\) and is indicated especially in patients who are intolerant of penicillamine or have clinical features indicating potential intolerance (history of renal disease of any sort, congestive splenomegaly causing severe thrombocytopenia, or autoimmune tendency). Neurologic worsening after beginning treatment with trientine has been reported but appears much less common than with penicillamine. Trientine has also been shown to be an effective initial therapy for patients, even with decompensated liver disease at the outset.\(^{151,152}\)

Trientine has few side effects. No hypersensitivity reactions have been reported although a fixed drug reaction was observed in one patient. Pancytopenia has rarely been reported. Trientine also chelates iron, and their coadministration should be avoided since the complex with iron is toxic. A reversible sideroblastic anemia may be a consequence of over-treatment and resultant copper deficiency. Lupus-like reactions have also been reported in some WD patients treated with trientine; however, these patients were almost all uniformly treated previously with penicillamine, so the true frequency of this reaction when trientine is used *de novo* is unknown. In general adverse effects due to penicillamine resolve when trientine is substituted for penicillamine and do not recur during prolonged treatment with trientine. Use in patients with primary biliary cirrhosis revealed that trientine may cause hemorrhagic gastritis, loss of taste, and rashes.\(^{153}\) Recent evidence suggests that copper deficiency induced by trientine can result in iron overload in livers of patients with WD, similar to that observed for penicillamine.\(^{154}\)

Typical dosages are 750 to 1,500 mg/d in 2 or 3 divided doses, with 750 or 1,000 mg used for maintenance therapy. In children the weight-based dose is not established, but the dose generally used is 20 mg/kg/d rounded off to the nearest 250 mg, given in 2 or 3 divided doses. As
for penicillamine, trientine should be administered 1 hour before or 2 hours after meals. Taking it closer to meals is acceptable if this ensures compliance. Trientine tablets are not stable for prolonged periods at high ambient temperatures, a problem for patients traveling to warm climates.

Adequacy of treatment is monitored by measuring 24-hour urinary copper excretion while on treatment. This should run in the vicinity of 200 to 500 μg (3-8 μmoles) per day on treatment. Additionally, estimate of nonceruloplasmin-bound copper may show normalization of the nonceruloplasmin-bound copper concentration with effective treatment.

**Zinc.** Zinc was first used to treat WD by Schouwink in Holland in the early 1960s. Its mechanism of action is different from that of penicillamine and trientine: zinc interferes with the uptake of copper from the gastrointestinal tract. Zinc induces enterocyte metallothionein, a cysteine-rich protein that is an endogenous chelator of metals. Metallothionein has greater affinity for copper than zinc and thus preferentially binds copper present in the enterocyte and inhibits its entry into the portal circulation. Once bound, the copper is not absorbed but is lost into the fecal contents as enterocytes are shed in normal turnover. Since copper also enters the gastrointestinal tract from saliva and gastric secretions, zinc treatment can generate a negative balance for copper and thereby remove stored copper. Zinc may also act by inducing levels of hepatocellular metallothionein.

Zinc has very few side effects. Gastric irritation is the main problem and may be dependent on the salt employed. Hepatic deterioration has been occasionally reported when zinc was commenced, fatal in one case. Zinc may have immunosuppressant effects and reduce leukocyte chemotaxis, but one study found no adverse effect on lymphocyte function with chronic use. Elevations in serum lipase and/or amylase may occur, without clinical or radiologic evidence of pancreatitis. Neurologic deterioration is uncommon with zinc. Whether high-dose zinc is safe for patients with impaired renal function is not yet established.

Although zinc is currently reserved for maintenance treatment, it has been used as first-line therapy, most commonly for asymptomatic or presymptomatic patients. It appears to be equally effective as penicillamine but much better tolerated. Reports of extensive series of adults with WD indicate good efficacy. A child who presented with ascites and coagulopathy was effectively treated only with zinc; a few other favorable reports in children have appeared. Combination treatment with trientine plus zinc or penicillamine plus zinc in which the chelator and the zinc are given at widely spaced intervals during the day has been advocated but not yet reported in rigorously designed series.

Dosing is in milligrams of elemental zinc. For larger children and adults, 150 mg/d is administered in 3 divided doses. Compliance with the 3 times per day dosage may be problematic, and it has to be taken at least twice daily to be effective. The actual salt used does not make a difference with respect to efficacy but may affect tolerability. Acetate may cause the least gastrointestinal distress, and gluconate may be more tolerable than sulfate. For smaller children less than 50 kg in body weight, the dose is 75 mg/d in 3 divided doses, and dose is poorly determined for children under 5 years of age. Taking zinc with food interferes with zinc absorption and effectiveness of treatment, but dose adjustments can be employed to compensate for this effect if taking zinc around mealtime ensures compliance.

Adequacy of treatment with zinc is judged by clinical and biochemical improvement and by measuring 24-hour urinary excretion of copper, which should be less than 75 μg (1.2 μmoles) per 24 hours on stable treatment. Additionally, estimate of nonceruloplasmin-bound copper shows normalization of the nonceruloplasmin-bound copper concentration with effective treatment. Urinary excretion of zinc may be measured from time to time to check compliance.

**Antioxidants.** Antioxidants, mainly vitamin E, may have a role as adjunctive treatment. Serum and hepatic vitamin E levels have been found to be low in WD. Symptomatic improvement when vitamin E was added to the treatment regimen has been occasionally reported but no rigorous studies have been conducted.

**Diet.** Foods with very high concentrations of copper (shellfish, nuts, chocolate, mushrooms, and organ meats) generally should be avoided, at least in the first year of treatment. Diets deficient in copper may delay the onset of the disease and control disease progression, but dietary management is not recommended as sole therapy. Consultation with a dietitian is advisable for practicing vegetarians. Well water or water brought into the household through copper pipes should be checked for copper content, but in general, municipal water supplies do not have to be checked. A water purifying system may be advisable if the copper content of the water is high. For those with copper pipes, it is important to flush the system of stagnant water before using water for cooking or consumption.

**Recommendations:**

(13) Initial treatment for symptomatic patients should include a chelating agent (penicillamine or trientine) (II).

(14) Treatment of presymptomatic patients or maintenance therapy of successfully treated symptomatic pa-
tients can be accomplished with the chelating agent penicillamine or trientine, or with zinc (II).

**Tetrathiomolybdate.** Tetrathiomolybdate is another chelating agent currently undergoing evaluation as an initial treatment of patients with neurologic symptoms. The first reports on the use of tetrathiomolybdate in this setting suggest no worsening of neurologic symptoms and a rapid reduction in circulating nonceruloplasmin-bound copper during the first 8 weeks of therapy. Currently this medication remains experimental in the United States and it is not commercially available.

**Treatment in Specific Clinical Situations**

**Asymptomatic Patients.** For asymptomatic or presymptomatic patients identified through family screening, treatment with a chelating agent, such as D-penicillamine or with zinc is effective in preventing disease symptoms or progression. Whether D-penicillamine or zinc should be used in presymptomatic children under the age of 3 years has not been determined.

**Maintenance Therapy.** After adequate treatment with a chelator, stable patients may be transitioned to treatment with zinc. In general, such patients will have been treated for 1 to 5 years. They will be clinically well, with normal serum aminotransferases and hepatic synthetic function, nonceruloplasmin-bound copper concentration in normal range, and 24-hour urinary copper repeatedly in the range of 200 to 500 μg (3-8 μmoles) per day on treatment. The advantages of long-term treatment with zinc include that it is more selective for removing copper than penicillamine or trientine and is associated with few side effects. Adequate studies regarding the timing of this change-over in treatment are not available. No matter how well a patient appears, treatment should never be terminated indefinitely. Patients who discontinue treatment altogether risk development of intractable hepatic decompensation.

**Fulminant Hepatic Failure.** Patients with fulminant hepatic failure due to WD require liver transplantation, which is life saving. To help determine which patients with acute hepatic presentations will not survive without liver transplantation, Nazer et al. developed a prognostic score whose components include serum bilirubin, serum AST, and prolongation of prothrombin time above normal; patients with a score of 7 or greater did not survive in their series of patients with WD. Until transplantation can be performed, plasmapheresis and exchange transfusion or hemofiltration or dialysis may protect the kidneys from copper-mediated tubular damage. Albumin dialysis was shown to stabilize patients with fulminant hepatic failure due to WD and delay, but not eliminate, the need for transplantation. The MARS ultrafiltration device may also be efficacious in this setting.

**Pregnancy.** In pregnant women, treatment must be maintained throughout the course of pregnancy for all patients with WD. Interruption of treatment during pregnancy has resulted in fulminant hepatic failure. Experience to date indicates that the chelating agents (both penicillamine and trientine) and zinc salts have been associated with satisfactory outcomes for the mother and fetus. The occurrence of a few birth defects has been noted infrequently in offspring of treated patients; however, the rarity of this disorder has made it difficult to determine whether this is different from the frequency for the occurrence of these defects in the population at large. The dosage of zinc salts is maintained throughout without change; however, dosages of chelating agents should be reduced to the minimum necessary during pregnancy, especially for the last trimester, to promote better wound healing if cesarean section is performed. Such a dose reduction might be on the order of 25% to 50% of the prepregnancy dose.

**Liver Transplantation.** Orthotopic liver transplantation (OLT) is indicated for all WD patients with decompensated liver disease unresponsive to medical therapy, and it is the only effective option for those who present with fulminant hepatic failure. OLT corrects the hepatic metabolic defects of WD and may serve to initiate normalization of extrahepatic copper disposition. One-year survival following OLT ranges from 79% to 87%, and those who survive this early period continue to survive long term. While the vast majority of patients undergoing liver transplantation for WD have received cadaveric donor organs, living donor transplantations can be performed. In one study it was found that successful live donor transplantation was possible even when the donor is a family member heterozygous for WD.

Less definite indications for OLT exist for patients with severe neurologic disease. Some individuals transplanted for decompensated cirrhosis have had psychiatric or neurologic symptoms, which improved following OLT. There are also a few reports of other individuals transplanted for neurologic disease that improved after OLT but detailed data on the neurologic evaluations of these patients are not available. Liver transplantation is not recommended as primary treatment for neurologic WD since the liver disease is stabilized by medical therapy in most of these individuals, and outcomes with liver transplantation are not always beneficial.

**Recommendations:** (15) Patients with fulminant hepatic failure or patients with severe liver disease unreaspon-
sive to chelation treatment should be treated with liver transplantation (II).

(16) Treatment for WD should be continued during pregnancy, but dosage reduction is advisable for D-penicillamine and trientine (III).

(17) Treatment is lifelong and should not be discontinued, unless a liver transplantation has been performed (II).

**Treatment Targets and Monitoring of Treatment.**

The goal of treatment monitoring is to confirm clinical and biochemical improvement, ensure compliance with therapy, and identify adverse side effects in a timely fashion. The frequency of monitoring of patients may vary for patients, but at a minimum should be performed twice a year. More frequent monitoring is needed for patients during the initial phase of treatment, for those experiencing worsening of symptoms or side effects of medications, and in individuals suspected of noncompliance with therapy. Physical examinations should look for evidence of liver disease and neurologic symptoms. Repeat examination for Kayser-Fleischer rings should be performed if there is a question of patient compliance as their appearance or reappearance in a patient in whom they were absent may portend the onset of symptomatic disease. For patients on penicillamine, cutaneous changes should be sought on physical examination. A careful history should also include questioning for psychiatric symptoms, especially depression.

Laboratory testing should include liver biochemistries including tests of hepatic synthetic function and indices of copper metabolism (serum copper and ceruloplasmin); the estimated serum nonceruloplasmin-bound copper may provide the best guide to treatment efficacy. Twenty-four–hour urinary copper excretion while on medication reflects overall exchangeable copper and is helpful for monitoring compliance. For patients taking D-penicillamine or trientine this should run 200 to 500 μg (3-8 μmoles) per day, and for patients on zinc it should be no more than 75 μg (1.2 μmoles) per day. Compliance in patients taking zinc can also be checked by measuring serum zinc or 24-hour urinary zinc excretion. The total blood count and differential should be monitored in all patients on chelators, and a urinalysis should be performed regularly to ensure safety.

Long-term outcome is dependent on adherence to lifelong treatment. Patients with WD who commence treatment before onset of symptomatic hepatic or neurologic disease have an excellent long-term prognosis and rarely develop symptoms. Appearance of hepatic or neurologic disease in these patients demands investigation of adequate adherence to therapy. Symptomatic patients may expect to stabilize or improve on treatment. A minority of patients with neurologic disease experience worsening with initiation of therapy: some stabilize but some worsen despite treatment. The prognosis for patients with liver disease who adhere to effective treatment is excellent, even if cirrhosis was present at the time of diagnosis.

**Recommendations:** (18) For routine monitoring, serum copper and ceruloplasmin, liver biochemistries and international normalized ratio, and physical examination should be performed regularly (III).

(19) Twenty-four–hour urinary excretion of copper while on medication should be measured yearly, or more frequently if there are issues of compliance or if dosage of medications is adjusted. The serum nonceruloplasmin-bound copper may be estimated in these situations (III).

(20) Patients receiving chelators require a complete blood count with differential and urinalysis regularly no matter how long they have been on treatment (III).

**Acknowledgment:** The authors extend their thanks to their mentors, Dr. Irmin Sternlieb and the late Dr. Andrew Sass-Kortsak, their colleagues and patients for their many contributions.
